We discuss the flavor conversion of neutrinos from core collapse supernovae that have oxygen-neon-magnesium (ONeMg) cores. Using the numerically calculated evolution of the star up to 650 ms post bounce, we find that, for the normal mass hierarchy, the electron neutrino flux in a detector shows signatures of two typical features of an ONeMg-core supernova: a sharp step in the density profile at the base of the He shell and a faster shock wave propagation compared to iron core supernovae. Before the shock hits the density step ($t \lesssim 150$ ms), the survival probability of electron neutrinos above ~ 20 MeV of energy is about ~ 0.68 , in contrast to values of ~ 0.32 or less for an iron core supernova. The passage of the shock through the step and its subsequent propagation cause a decrease of the survival probability and a decrease of the amplitude of oscillations in the Earth, reflecting the transition to a more adiabatic propagation inside the star. These changes affect the lower energy neutrinos first; they are faster and more sizable for larger θ_{13} . They are unique of ONeMg-core supernovae, and give the possibility to test the speed of the shock wave. The time modulation of the Earth effect and its negative sign at the neutronization peak are the most robust signatures in a detector.

I. INTRODUCTION

A core collapse supernova is mainly a neutrino phenomenon. The $\sim 3 \cdot 10^{53}$ ergs of energy liberated in the collapse are radiated by neutrino emission from a thermal surface, the neutrinosphere.

While the neutrino flux at the neutrinosphere is fairly independent of the star's properties, the neutrino flux we receive on Earth does depend on those. Indeed, neutrino oscillations are sensitive to the profile of the matter density that the neutrinos encounter on their path. This makes them a very valuable tool to do a tomography of the star, in a way that depends on the neutrino mass spectrum and mixing matrix. An example is the possibility to use neutrinos to track the distortions in density caused by the propagation of the shock wave inside the star [1]. The sensitivity of the shock effects to the mixing θ_{13} would provide a powerful test of it [2, 3, 4, 5, 6].

An interesting implication of neutrino oscillations as tools for star tomography is the possibility to distinguish between different types of supernovae that differ in their density profile. In particular, neutrinos can distinguish [7] between a supernova with an iron core (Fe-core supernova) and one with an oxygen-neon-magnesium core (ONeMg-core supernova), for which the density distribution and the shock propagation are completely different.

Stars in the mass window between roughly eight and ten solar masses are expected to develop ONeMg cores, which may undergo gravitational collapse before Ne ignition due to rapid electron captures on ^{24}Mg and ^{20}Ne and may thus explode as so-called electron-capture supernovae (see [8] for a recent study with a summary of previous works). This distinguishes such stars from the more massive supernova progenitors, whose evolution through all stages of hydrostatic nuclear burning leads to the for-

mation of an iron core at their center. ONeMg cores are bounded by an extremely steep density gradient (which we will call “density step” in the following), which differs drastically from the much shallower density profiles around iron cores (see, e.g., figs. 1 of [9, 10]).

The steep density decline allows the hydrodynamic bounce-shock to expand continuously, a fact that is favorable for efficient neutrino heating in the post-shock layer and thus facilitates neutrino-driven explosions even in spherically symmetric simulations [11, 12]. Traveling down the density step, the outgoing shock also accelerates to much higher velocities than in the central regions of Fe-core supernovae. Despite the large difficulties in modeling their progenitor evolution, ONeMg core collapses have received quite some interest, in particular because of repeated speculations that they might be the long-sought site of the formation of r-process elements (e.g., [13, 14, 15, 16, 17]) and because of their possible link to the supernova of 1054 A.D., which gave birth to the Crab nebula (e.g., [18, 19, 20, 21, 22]). The number of similar stellar death events could account for a fair fraction of all supernovae. Poelarends et al. [8] estimate that about 4% of the stellar core collapses in the local universe might be of this kind, but the uncertainties in modeling the stellar evolution in the initial mass range between 6 and $12 M_{\odot}$ are significant and therefore the authors do not exclude a contribution of even 20% to all supernovae.

To identify or exclude the oscillation signatures of an ONeMg-core supernova in an observed neutrino burst would be an important, unprecedented, test of stellar models and in particular of the existence of a density step in the interior of the star. It would be a necessary part of any data analysis aimed at reconstructing the originally produced neutrino fluxes (before oscillations)

and information on neutrino masses and mixings.

But what are these signatures?

Very recently Duan, Fuller, Carlson, and Qian have pointed out [7] that, due to the step in density, for ONeMg-core supernovae the neutronization peak (a peak in the ν_e luminosity at about 10 ms post bounce) would not disappear regardless of the value of θ_{13} . In contrast, for θ_{13} just below the current bound disappearance due to $\nu_e \rightarrow \nu_\mu, \nu_\tau$ conversion is expected for Fe-core supernovae [3, 23, 24]. Duan et al. also pointed out how the conversion pattern is more complex for a ONeMg-core supernova, because neutrino-neutrino scattering influences the resonant conversion driven by matter. The initial study in [7], as well as the analytical elaboration in [25], were restricted to the neutrino flux at the neutronization peak and to relatively large θ_{13} . Beyond these, the subject of neutrino conversion inside a ONeMg-core supernova remains to be explored.

Here we give a in depth – even though far from comprehensive – study of neutrino oscillations in ONeMg-core supernovae. We present the first discussion of shock wave effects for this type of supernova, using a numerical calculation of the density profile and of the neutrino fluxes, as they evolve over several hundreds of milliseconds.

We describe a variety of conversion effects that could appear at different times depending on the value of θ_{13} and on whether the detector is shielded by the Earth when the neutrino burst reaches it. We also address the question of what features could be observable and how. A first goal is to outline what combination of signatures one should look for to test models of ONeMg-core supernovae; another purpose is to describe the phenomena that should be taken into account when analyzing neutrino data from a ONeMg-core supernova.

The paper opens with generalities on ONeMg-core supernovae and details on our numerical model (sec.II). In sec. III we give a discussion of conversion effects, followed by our results in sec. IV. A discussion on the implications of our findings closes the paper in sec. V.

II. OXYGEN-NEON-MAGNESIUM-CORE SUPERNOVAE: THE MODEL

The interior structure of stars in the range $\sim 8\text{--}10 M_\odot$ ($M_\odot = 1.99 \times 10^{30}$ kg is the mass of the Sun) is distinctively different from that of more massive supernova progenitors: their ONeMg core is surrounded by a thin carbon and oxygen shell and an even thinner helium layer. The density gradient in this surface region of the core (at around 1000 Km) is extremely steep; the density can drop by nearly seven orders of magnitude within only 300 Km. This is visible from Fig. 1, where the line corresponding to time $t = 0$ displays the electron number density profile of the innermost region of the $8.8 M_\odot$ progenitor star used as initial model for the core-collapse and supernova simulations this work is based on (baryon densities in the core and its surface layer can be obtained by multiplica-

tion by a factor of 2). The ONeMg core of this star was evolved to the onset of collapse by Nomoto [26, 27] and was more recently extended outside of the thin He shell by a hydrostatic hydrogen envelope [28].

FIG. 1: Snapshots of the electron density profile at $t = 0, 50, 100, \dots, 700$ ms (lines from top to bottom at their left end, except for the inverted curves for $t = 0$ and $t = 50$ ms). The positions of the supernova shock for $t \geq 200$ ms coincide essentially with the lower right footprints of the profiles. For $t = 300$ ms we also plot the effective number density of neutrinos (dashed curve, see Eq. (4)), which is responsible for the effects of neutrino-neutrino forward scattering. The two horizontal lines represent the densities corresponding to the two MSW resonances for a neutrino of 20 MeV energy.

The updated progenitor model was followed through collapse and explosion with the neutrino-hydrodynamics code VERTEX [29, 30]. Details of the employed input physics and information about the supernova dynamics can be found in the works by Kitaura et al. [12] and Janka et al. [9, 10]. Figure 1 provides an overview of the evolution of the electron density (n_e) profile in steps of 50 ms until 700 ms after the start of a spherically symmetric (1D) simulation. The core bounce happens at $t = 53.6$ ms and the explosion sets in at about 130 ms (to be recognized from positive velocities developing in the post-shock layer).

For $t = 100$ ms the step in density induced by the shock is visible at $r \sim 130$ Km. The shock front advances outward rapidly, reaching $r \sim 500$ Km at $t \lesssim 150$ ms and meeting the base of the He shell (at $r \sim 1100$ Km and $n_e \sim 4 \times 10^{26} \text{ cm}^{-3}$) less than 10 ms later. At this point, the shock accelerates even more and travels essentially with the speed of light until it is gradually decelerated again by running into the flatter density profile of the hydrogen envelope and sweeping up matter from the progenitor star. At the end of the computed evolution, the shock has reached a radius of more than 2×10^5 Km (Fig. 1).

As a consequence of the differential collapse of the core, starting with the innermost regions and only gradually encompassing layers farther away from the center, the

density step is significantly flatter at the time when the shock hits the ONeMg-core surface and passes through the base of the He shell. For the first roughly 100 ms after the shock passage through the step, the density profile therefore appears essentially smooth. The ejecta in the region of the previous density step then expand with nearly uniform and constant velocity ($\sim 2\text{--}3 \times 10^4 \text{ cm s}^{-1}$) and the width of this layer (1000–2000 km) is preserved. At later times, however, the profile appears to steepen again because of the dramatically increasing radial scale and the resulting relative decrease of the ratio of width to radius of the shell. The relics of the original density step of the pre-collapse core can therefore still be recognized as an outward moving step-like structure on the density profile of the shock-accelerated and expanding ejecta of the supernova explosion.

FIG. 2: Neutrino luminosities (top) and average energies (bottom) before oscillations. The ν_x ($\nu_x = \nu_\mu, \nu_\tau, \bar{\nu}_\mu, \bar{\nu}_\tau$) luminosity is per species, so the total luminosity in the non-electron flavors is four times the one plotted here. The average energy is defined as the ratio of energy flux to number flux.

The time evolution of the neutrino luminosities and of the mean spectral energies (measured at a radius of $r = 400 \text{ km}$ for an observer in the laboratory frame), without including flavor conversion, is shown in Fig. 2. The displayed data are from a two-dimensional (2D) simulation (assuming axisymmetry around the polar grid axis) of an ONeMg-core supernova, which was followed

until roughly 200 ms after core bounce. The explosion dynamics of the 1D and 2D models is very similar and the density profiles as shown in Fig. 1 basically also apply for the 2D model after averaging over latitudes (thus wiping out inhomogeneities associated with convective overturn in the neutrino-heating layer around the neutron star). In contrast to 1D results, the neutrino luminosities and mean energies from the 2D model include the modifications caused to the neutrino emission by convective energy transport inside the nascent neutron star. This plays a role later than a few ten milliseconds after core bounce and leads to slightly (about 10%) enhanced electron neutrino and in particular muon and tau neutrino luminosities, a slightly reduced electron antineutrino luminosity, and somewhat lowered ($\sim 0.5\text{--}1 \text{ MeV}$) mean energies of all radiated neutrinos [31].

Figure 2 shows that the luminosities, flavor composition, and mean spectral energies of the neutrinos reveal the well known behavior: the peak in ν_e associated with the neutronization burst, the slower rise of the $\bar{\nu}_e$ and ν_x ($\nu_x = \nu_\mu, \nu_\tau, \bar{\nu}_\mu, \bar{\nu}_\tau$) luminosities, and the hierarchy of the ν_e , $\bar{\nu}_e$ and ν_x average energies. The main difference compared to Fe-core supernovae is the absence of an extended phase of post-bounce accretion of the forming neutron star and therefore the lack of the corresponding accretion plateau in the neutrino luminosities after the ν_e shock-breakout burst.

The 2D simulation was only carried to about 200 ms after bounce. For our analysis of neutrino oscillation effects at later times until the end of the 1D simulation at $\sim 650 \text{ ms}$ post bounce, we will take the neutrino luminosities and mean energies to be roughly constant. This is a reasonably good assumption because of the mentioned absence of accretion and the only slow, quasi-steady evolution of the settling neutron star. Moreover, our discussion will mostly concentrate on matter-of-principle effects and the details of the neutrino emission properties will not be relevant.

The fluxes in Fig. 2 will be used as initial conditions for the calculation of neutrino oscillations, making the assumption that the neutrino luminosities and mean energies are constant outside of the neutrinosphere.

In our calculations, we model the neutrino energy spectra following Keil, Raffelt and Janka [32]:

$$\frac{dN}{dE} \simeq \frac{(1 + \alpha)^{1+\alpha} L}{\Gamma(1 + \alpha) E_0^2} \left(\frac{E}{E_0} \right)^\alpha e^{-(1+\alpha)E/E_0}, \quad (1)$$

where E_0 is the average energy and L the luminosity. We take $\alpha = 2.3$, for which the spectrum is close to a Fermi-Dirac distribution. The power law in Eq. (1) is adequate in the fact that it reproduces well the numerical results of sophisticated neutrino transport (though by choosing a constant value for α we neglect the detailed evolution of the spectral shape provided by the simulation results) [32].

III. FLAVOR CONVERSION IN THE STAR AND IN THE EARTH: GENERALITIES

Neutrino conversion in supernovae is particularly complex due to the interplay of several effects. Here we review them briefly, in the measure needed to highlight the phenomena that are distinctive of a ONeMg-core supernova. We refer to the literature for more complete reviews (e.g., [24, 33, 34]).

The flavor evolution of neutrinos inside the star and in the Earth is described by a Hamiltonian that contains three terms. The first is the kinetic term, which depends on three mixing angles θ_{ij} , a CP-violating phase δ_{CP} , and two independent mass squared splittings, Δm_{ji}^2 , where the indices $i, j = 1, 2, 3$ refer to the three mass eigenstates ν_1, ν_2, ν_3 . The three characteristic oscillation frequencies associated with the kinetic term are:

$$\omega_{ji} = \frac{\Delta m_{ji}^2}{2E}, \quad (2)$$

with E the neutrino energy. We use the standard parametrization of the mixing matrix, with the values $\sin^2 \theta_{12} = 0.32$, $\Delta m_{21}^2 = 8 \cdot 10^{-5} \text{ eV}^2$, $|\Delta m_{31}^2| = 3 \cdot 10^{-3} \text{ eV}^2$, and $\sin^2 \theta_{13} \leq 2 \cdot 10^{-2}$ (see e.g., the summary in [35] and references therein). Notice that θ_{13} has not been measured yet [36, 37], and that Δm_{31}^2 is known only in absolute value. The case of positive (negative) Δm_{31}^2 is called *normal* (*inverted*) mass hierarchy. The phase δ_{CP} can be ignored here, as it does not influence the relevant probabilities for equal ν_μ and ν_τ fluxes [38, 39].

The second and third terms relevant for neutrino conversion are due to neutrino forward scattering (refraction) on electrons and on neutrinos. Their characteristic frequencies are

$$\omega_e = \sqrt{2} G_F n_e, \quad \omega_\nu = \sqrt{2} G_F n_\nu^{eff}, \quad (3)$$

where n_e is the number density of electrons along the trajectory of the neutrinos, and n_ν^{eff} is the effective number density of neutrinos. It is defined as (see e.g., [34]):

$$n_\nu^{eff} = N_\nu \frac{1}{2} \left[1 - \sqrt{1 - \left(\frac{R}{r} \right)^2} \right]^2, \quad (4)$$

where r is the radial coordinate, R is the radius of the neutrinosphere, and N_ν is the total number density of neutrinos and antineutrinos of all flavors at the neutrinosphere: $N_\nu = \sum_{\alpha=e,\mu,\tau} (N_\alpha + \bar{N}_\alpha)$. The self-interaction term from neutrino-neutrino scattering generates non-linear effects that only recently have been studied in detail in the context of supernovae [7, 25, 34, 40, 41, 42, 43, 44, 45, 46, 47, 48, 49].

The character of the neutrino conversion is roughly determined by the relative size of the different frequencies ω_{ji} , ω_e , and ω_ν . Each of the two refraction terms is relevant if its frequency is comparable or larger than the kinetic (vacuum) ones. The more terms contribute simultaneously, the higher is the complexity of the conversion

pattern. Fig. 1 allows to compare the strengths of the vacuum and refraction terms. Together with the electron density profile at different times, the figure shows the values of n_e for which the conditions $\omega_{21} = \omega_e$ and $\omega_{31} = \omega_e$ are realized for $E = 20 \text{ MeV}$. For small mixing angles (as it is the case for θ_{13}), these well approximate the condition for the MSW resonance [23, 50, 51, 52]. We also plot the effective neutrino number density, $n_\nu^{eff}(r)$ for $t = 300 \text{ ms}$ and $R = 60 \text{ Km}$. This quantity is smaller (larger) at later (earlier) times, as follows from fig. 2.

From fig. 1 we identify two different scenarios: the stage before the shock reaches the He shell, $t \lesssim 150 \text{ ms}$, and the later times, $t \gtrsim 150 - 200 \text{ ms}$. These phases will be called *pre-shock* and *post-shock* respectively from here on. In what follows we discuss them for the propagation of neutrinos with the normal mass hierarchy, which is the most transparent and sufficient to illustrate the main effects.

A. The late stage: post-shock

Let us first consider the late, post-shock phase, for $t \gtrsim 300 \text{ ms}$. For this, in the most internal part of the star ($r \simeq 100 \text{ Km}$) both the neutrino-electron and the neutrino-neutrino scattering terms exceed the vacuum one and are comparable to each other. In general, they both affect oscillations substantially. As the neutrinos propagate out to larger radii, the influence self-interaction is strong over a typical distance of $10^2 - 10^3 \text{ Km}$. At $r \simeq 3000 \text{ Km}$, the neutrino-neutrino term, ω_ν , falls below the vacuum frequency ω_{21} , and thus becomes negligible, marking the end of self-interaction effects. Since the electron number density decreases more slowly with the radius, at this distance the neutrino-electron term is still large and dominates over the vacuum one by at least one order of magnitude. Only at radius $r \gtrsim 4 - 5 \cdot 10^3 \text{ Km}$ we have $\omega_{31} \sim \omega_e$, which drives the inner MSW resonance. Another resonance, driven by $\omega_{21} \sim \omega_e$, follows at even larger radius, $r \gtrsim 8 \cdot 10^3 \text{ Km}$, beyond which all matter effects are negligible. The separation between the distance of decoupling of the self-interaction effects and the position of the MSW resonances, as well as the separation between the two resonances themselves, increases with time. Thanks to this separation, the phase of collective effects, driven by neutrino-neutrino scattering, and the MSW resonances are decoupled.

A scenario with these characteristics has been studied, for a Fe-core supernova, by Fogli et al. [34]. They found that, beyond the region where self-interaction effects end, the neutrino spectra are unchanged for the normal mass hierarchy. Such conclusion has little dependence on θ_{13} and on the specific electron density profile, as long as the condition $\omega_e \gg \omega_{31}$ is satisfied over the distance of effectiveness neutrino-neutrino scattering [34] (see also [42, 43] for further discussions). It is supported by analytical arguments based on the minimization of potential

energy of a spin in a magnetic field (e.g., [34, 42, 44, 47]). Only with the violation of the matter-dominance condition (which is not our case) a swap of the ν_e and ν_μ / ν_τ spectra might occur below a critical energy $E_C \lesssim 10$ MeV [46]. Even in the implausible case that a swap with $E_C \lesssim 10$ MeV occurs in our scenario, such swap would depend only indirectly on the electron density, with no strong sensitivity to the density structure of a ONeMg-core supernova.

For all these reasons, we consider it adequate here to consider unchanged neutrino spectra immediately after (in radial distance) the end of self interaction effects, and focus of the physics of the MSW-driven transformation, which, thanks to its direct and resonant dependence on n_e , is a much more sensitive probe of the matter distribution inside the star. As will be seen, the most interesting effects of the MSW resonances are at high energy ($E \gtrsim 30$ MeV), and thus are not influenced by a possible swap at low energy.

After the MSW-driven conversion, the flux of electron neutrinos at Earth, F_e , can be written in terms of the fluxes without oscillations, F_e^0 and F_x^0 ($x = \mu, \tau$), as:

$$F_e = pF_e^0 + (1 - p)F_x^0, \quad (5)$$

where p denotes the ν_e survival probability. This probability is given by [24]:

$$p \simeq P_H [\cos^2 \theta_{12} P_L + \sin^2 \theta_{12} (1 - P_L)] . \quad (6)$$

Here P_H (P_L) is the probability of transition between the eigenstates ν_3 and ν_2 (ν_2 and ν_1) of the Hamiltonian in the higher density (lower density) MSW resonance. P_H depends on θ_{13} and on the derivative of the electron number density, calculated at the point r_{res} where $\omega_{31} = \omega_e$ (see e.g., [53]):

$$P_H = \frac{e^{\chi \cos^2 \theta_{13}} - 1}{e^{\chi} - 1}, \quad \chi \equiv -2\pi \frac{\Delta m_{31}^2}{2E} \left[\frac{1}{n_e(r)} \frac{dn_e(r)}{dr} \right]_{r=r_{res}}^{-1}. \quad (7)$$

P_L obeys the same expression with the replacements $\omega_{31} \rightarrow \omega_{21}$, $\theta_{13} \rightarrow \theta_{12}$ and $\Delta m_{31}^2 \rightarrow \Delta m_{21}^2$. We can see that the survival probability varies between $p = 0$ and $p = \cos^2 \theta_{12}$ (numerically, between $p = 0$ and $p = 0.68$), for P_H and P_L varying in the allowed range from 0 (*adiabatic* propagation) to 1 (completely *non-adiabatic* propagation). The derivative of the density profile in Eq. (7) encodes the sensitivity of the MSW effect to the matter distribution: the amount of flavor conversion depends on how rapidly the electron density changes along the neutrino trajectory and on the size of the mixing angle. Steeper profiles and smaller mixings correspond to stronger violation of adiabaticity.

The post-shock phase can be divided in an *early* part, $t \lesssim 650$ ms, and a *late* one, $t \gtrsim 650$ ms. The late part begins when, accelerated by the shock, the He shell has

traveled outwards and expanded to lower density, to a degree that the density step associated with it does not extend to the resonance density anymore, and thus becomes irrelevant for neutrino conversion. In coincidence with this transition to a shallower density profile, we expect the MSW conversion to become more adiabatic. Such early transition in the direction from less to more adiabatic conversion is unique of a ONeMg-core supernova.

B. The early stage: pre-shock

Let us now discuss the more complicated pre-shock phase. Here, all the three frequencies are comparable at $r \simeq 10^3$ Km. Therefore the physics of the MSW resonances can not be decoupled from that of neutrino-neutrino scattering as in the post-shock phase. Moreover, the two resonances are spatially closer, to the point that the factorization of their effects may not be valid.

In ref. [7] the ν_e survival probability for this case was calculated numerically, for $\theta_{13} = 0.1$. It appears that, for the normal hierarchy, the probability can be described by transitions between the eigenstates of the Hamiltonian, in a way that resembles the simpler case of two spatially separated resonances without effects of neutrino-neutrino refraction. An important feature is the presence of sharp swaps in the energy spectrum, instead of the smoother transitions between adiabatic and non-adiabatic regimes that are expected in the pure MSW case as the neutrino energy increases.

In the limit of slowly varying neutrino density, the probability found in [7] has an analytical interpretation [25]: it is the result of collective MSW transitions – where the collective behavior is due to neutrino-neutrino scattering – followed, at lower density, by spectral swaps analogous to those already observed for other density profiles [40, 46]. The ν_e survival probability can be described with the same expression, Eq. (6), using effective values for P_H and P_L [68]. In first approximation, these behave as step functions, whose critical energies are determined by conservation laws [25, 49]. Specifically, the numerical result in [7] is reproduced by:

$$P_H = \begin{cases} 1 & \text{for } E > 12 \text{ MeV} \\ 0 & \text{otherwise} \end{cases} \quad P_L = \begin{cases} 1 & \text{for } E > 15 \text{ MeV} \\ 0 & \text{otherwise} \end{cases} \quad (8)$$

so that we have $p \simeq 0$ below 12 MeV and $p \simeq 0.68$ at $E \gtrsim 15$ MeV, with $p \simeq 0.32$ as intermediate value between the two.

While the dependence of the results on θ_{13} was not shown in [7], it was checked by the same authors [54] that the behavior $p = \cos^2 \theta_{12} \simeq 0.68$ at high energy (above a critical energy $E_C \lesssim 15$ MeV) is a generic feature even for smaller θ_{13} , reflecting the fact that the produced ν_e 's always emerge the star almost completely in the lightest

mass state, ν_1 . This can also be understood considering that in the limit $\theta_{13} \rightarrow 0$, the third mass state is a pure mixture of ν_μ and ν_τ , and therefore it decouples from the evolution of ν_e . This implies that the ν_e survival probability should depend only on the pair of states ν_2 and ν_1 . These have a ν_e content ranging from $\sin^2 \theta_{12} = 0.32$ to $\cos^2 \theta_{12} = 0.68$. A $\nu_2 \rightarrow \nu_1$ swap would produce a change in the survival probability from the lower to the higher of these two values.

Here we use the numerical result from ref. [7] for the survival probability. For $\theta_{13} = 0.1$, it applies well to our case because all the parameters match: our pre-shock density profile matches the one in [7] and the neutrino spectrum at the neutronization peak ($t \simeq 60$ ms) has a very similar average energy (12-13 MeV against the 11 MeV in [7]) [69]. For smaller θ_{13} , we consider the same result to be still applicable to the high energy range, in the light of the reasoning above. As it will appear shortly, the high energy range is where we expect the most robust signatures of conversion, namely the Earth regeneration.

Notice that we do not address the neutrino conversion at the instants of time that immediately precede and follow the shock passage through the density step, $t \sim 150 - 300$ ms. This is because in this interval the conversion pattern is highly complicated: the matter near the resonance density undergoes a quick acceleration to relativistic velocity with the passage of the shock, thus making relativistic corrections necessary [55]. Instead, for the same density, velocities are lower than 10% of the speed of light at later times. In addition to relativistic corrections, one would need to include all the oscillation terms (kinetic, electron scattering and self-interaction) simultaneously, as in the pre-shock phase. The combination of these effects would require a dedicated study that is postponed for the time being.

C. Oscillations in the Earth

In addition to conversion in the star, neutrinos from a supernova undergo oscillations inside the Earth. These oscillations are observable by a detector that is shielded by the Earth when the neutrino burst reaches it. They are driven by neutrino-electron scattering. The phase of oscillation depends on the solar parameters, θ_{12} and Δm_{21}^2 , while the amplitude reflects the pattern of conversion in the star. The difference between the ν_e flux in a detector with and without Earth shielding has the expression (valid for normal hierarchy) [24, 56]:

$$F_e^D - F_e = (F_e^0 - F_x^0) P_H (1 - 2P_L) f_{reg}. \quad (9)$$

Here f_{reg} is the *regeneration factor*. Up to terms proportional to $\sin^2 \theta_{13}$, f_{reg} is given by:

$$f_{reg} = P^\oplus(\nu_2 \rightarrow \nu_e) - \sin^2 \theta_{12}, \quad (10)$$

where $P^\oplus(\nu_2 \rightarrow \nu_e)$ is the probability that a state entering the Earth as ν_2 is detected as ν_e in the detector. In

the absence of Earth shielding, $P^\oplus(\nu_2 \rightarrow \nu_e) = \sin^2 \theta_{12}$ and $f_{reg} = 0$. The regeneration factor is an oscillatory function, and $f_{reg} \gtrsim 0$ with good approximation at all energies and zenith angles. Notice that Eq. (9) exhibits an elegant factorization of the several steps of the neutrino propagation from production to detection: the first factor describes the originally produced fluxes, the second the higher density resonance, the third the low density resonance and the fourth the effect of the Earth. This factorization makes the Earth effect particularly transparent, and the oscillatory character makes it an unambiguous signature of neutrino flavor conversion, that can not be confused with astrophysical effects.

Here we calculate the oscillations in the Earth using Eq. (9) with P_L and P_H as described above for the two regimes (pre and post shock), and with f_{reg} from the accurate numerical calculation in [56].

IV. CONVERSION OF NEUTRINOS FROM AN ONEMG-CORE SUPERNOVA: RESULTS

A. Probabilities

From the previous sections, one can see two oscillation effects that are distinctive of a ONeMg-core supernova. One of them is the influence on the adiabaticity of conversion of the sharp gradient in density that marks the oxygen-helium transition in the star. One expects strong adiabaticity breaking even for relatively large θ_{13} , in contrast to Fe-core supernovae. The second effect is the time variation of the oscillation probabilities within the first hundreds of milliseconds of the burst, associated with the variation of the density profile with the shock passage. In Fe-core supernovae shock effects appear at much later times. Below we illustrate these effects in detail and compare them to the results for Fe-core supernovae from the literature (e.g., [24, 33, 34]). In our calculations we have used the results of Duan et al. [7] for the pre-shock phase, and the density profiles in fig. 1, together with the analytics in sec. III for the post-shock times.

Let us begin with the jumping probability P_H . In fig. 3 P_H is plotted as a function of $\sin^2 \theta_{13}$ for $E = 20$ MeV and for three representative times, one in the pre-shock phase ($t = 60$ ms [70]), one in the early post-shock phase ($t = 450$ ms) and one in the late post-shock stage ($t = 700$ ms). The same function for a Fe-core supernova (at $t \lesssim 3$ s, from ref. [3]) is also shown for comparison.

We see essentially three regimes in θ_{13} :

1. *large*: $\sin^2 \theta_{13} \gtrsim 3 \cdot 10^{-3}$. The character of the conversion changes fast (within $\sim 200 - 300$ ms or so), turning from non-adiabatic in the pre-shock phase, to completely adiabatic afterward.
2. *intermediate*: $\sin^2 \theta_{13} \simeq 3 \cdot 10^{-5} - 3 \cdot 10^{-3}$. The character of conversion changes more slowly: it is completely non-adiabatic in the pre-shock phase, and after ~ 300 ms it is still at least partially

FIG. 3: The jumping probability P_H for $t = 60, 450, 700$ ms (solid curves, from upper to lower) as a function of $\sin^2 \theta_{13}$ for energy $E = 20$ MeV. The dashed line shows the same probability for a Fe supernova with the parameters in ref. [3].

non-adiabatic. Only in the late post-shock phase ($t \gtrsim 700$ ms) it may become completely adiabatic if $\sin^2 \theta_{13} \sim 3 \cdot 10^{-4} - 3 \cdot 10^{-3}$. In this range of mixing the three time intervals (pre-shock, post-shock early and post-shock late) can be distinguished.

3. *small*: $\sin^2 \theta_{13} \lesssim 3 \cdot 10^{-5}$. The conversion remains completely non-adiabatic at all times, with only a minor change in the transition from the early to the late post-shock phases.

Notice that only in the late post-shock stage the dependence of P_H on θ_{13} resembles the one of a Fe-core supernova, for which there is no time variation until much later times.

The jumping probability in the low density resonance, P_L , is found to be zero at all post-shock times, and is set to 1 before the shock for $E \gtrsim 12$ MeV, as discussed in sec. III. For a Fe-core supernova $P_L = 0$ at all times.

FIG. 4: The electron neutrino survival probability for $t = 60, 450, 700$ ms (solid, short dashed, and long dashed, respectively) and $\sin^2 \theta_{13} = 6 \cdot 10^{-4}$. $p = 0$ for a Fe-core supernova over the same time interval.

The behavior of P_L , combined with the results in fig. 3 for P_H , explains what we see in fig. 4, showing the energy

dependence of the survival probability p for $\sin^2 \theta_{13} = 6 \cdot 10^{-4}$ and no Earth shielding. In the transition from the pre- to the post-shock phases the probability decreases from ~ 0.68 to ~ 0.32 (asymptotic values at high energy) mostly as a consequence of the change in P_L . At later times, p goes to zero, beginning with the lower energy part of the neutrino spectrum. This appears in fig. 4: for $t = 700$ ms below $E \sim 22$ MeV we have $p = 0$, because for these energies the high density resonance is realized in the shallower part of the density profile, more internal with respect to the base of the He shell (regrouped after the shock passage). Instead, at higher energy the resonance is realized at lower density, on the density step. The step is moving outwards and becoming less dense, so the transition to $p \simeq 0$ moves to larger energy.

For small θ_{13} , $P_H \simeq 1$ at all times, and so the only change in p is due to the transition of P_L : the asymptotic value of p goes from ~ 0.68 to ~ 0.32 and retains this value at all later times.

For large θ_{13} , the probability p changes from $p \simeq 0.68$ to zero immediately after the shock passage, when P_H goes to zero.

FIG. 5: The ν_e survival probability as a function of time for $E = 20$ MeV and $\sin^2 \theta_{13} = 0.01, 6 \cdot 10^{-4}, 10^{-5}$ (solid, short dashed, and long dashed, respectively). The step-like structure reflects the fact that the oscillation effects were evaluated for density profiles in steps of 50 ms ($t = 0, 50, 100, \dots$ ms, middle points of the steps, see profiles of fig. 1). For $t \sim 150 - 300$ ms the figure is only schematic: it does not capture the full complexity of the conversion in accelerating matter when the shock passes through the density step (see sec. III B).

The features seen in fig. 4 appear also in fig. 5, where the time dependence of p is shown for fixed energy and different values of θ_{13} . The figure is a good quantitative description for the pre-shock and late post-shock phases ($t \gtrsim 300$ ms), while for the intermediate times it has only a schematic character. This is because it does not include a number of effects that are relevant when the matter at the base of the He shell is strongly accelerated by the shock (see sec. III B). The figure evidences clearly the general decline of the survival probability with time, up to minor deviations from the monotonic trend due to the minute details of the density profile at the MSW

resonance. It is also apparent that this decrease is faster for larger θ_{13} , as already noticed above.

The conversion pattern found for a ONeMg-core supernova is in contrast with that for a Fe-core supernova over the same time interval: in that case, the survival probability has no time dependence and ranges from $p = \sin^2 \theta_{12} \simeq 0.32$ to $p = 0$ depending on θ_{13} (fig. 3).

In the absence of Earth shielding, the observation of the oscillation effects could be challenging. Indeed, the measurement of a probability would be complicated by uncertainties in the original neutrino fluxes, and the shock-induced modulations of the probabilities could be masked by the natural time evolution of the neutrino spectra and luminosities. The best signature to look at would probably be the fate of the peak in the ν_e luminosity at $t \simeq 60$ ms: for large θ_{13} it disappears for a Fe-core supernova, but it survives for an ONeMg-core one [7]. A conclusion on this would require knowing θ_{13} , however. Looking for the progressive vanishing of p from lower to higher energy (fig. 4) might also be promising.

As it has already been pointed out for a Fe-core supernova [56, 57, 58], the Earth shielding can be a great advantage, because oscillations in the Earth have an unambiguous signature: oscillatory distortions in the observed neutrino energy spectrum. The very presence of the effect allows one to conclude on neutrino masses and mixing, even in the presence of uncertainties on the original neutrino fluxes.

FIG. 6: The relative Earth matter effect in the neutrino channel, at 60 degrees nadir angle, for $t = 60, 450, 700$ ms (solid-, short-dashed and long-dashed, respectively) and $\sin^2 \theta_{13} = 6 \cdot 10^{-4}$. For a Fe supernova and the same value of θ_{13} , the Earth effect is zero.

Fig. 6 shows the relative Earth effect, defined as $(F_e^D - F_e)/F_e$ (see Eq. (9)), for nadir angle of 60 degrees, an intermediate value of θ_{13} ($\sin^2 \theta_{13} = 6 \cdot 10^{-4}$) and the same instants of time as in the previous plots. The amplitude of the effect reflects the time evolution of P_H and P_L . In the pre-shock regime the amplitude is maximal, reaching $\sim 25\%$ effect at $E \simeq 56$ MeV. The effect is negative because, with $P_L \sim 1$, the term $(1 - 2P_L)$ is negative and

the flux contribution is positive, $F_e^0 - F_x^0 > 0$, reflecting the fact that ν_e dominates the flux at this stage.

In the early post-shock phase the effect is reduced in amplitude at low energy, where the conversion is partially adiabatic in the high density resonance. Notice that, with respect to the pre-shock phase, above $E \sim 15$ MeV there is a double change of sign in Eq. (9): one is caused by P_L changing from 1 to 0, and the other due to the transition from ν_e dominated to ν_x -dominated (at high energy) flux, meaning a change of sign in the term $F_e^0 - F_x^0$. The net Earth effect is again negative. Notice that the double change of sign is a unique feature of a ONeMg-core supernova: for any value of θ_{13} at $t = 60$ ms the relative Earth effect would be positive in a Fe supernova.

We stress that the two sign flips may occur at slightly different times, thus giving rise to an interesting sequence of sign changes in the Earth effect. It might also be possible to see the amplitude of the oscillations become smaller and then increase again if the transition of P_L from 1 to 0 is gradual and $P_L \simeq 1/2$ for a significant period of time and/or if the quantity $F_e^0 - F_x^0$ reaches a minimum in absolute value. To study if and how these time modulations happen is beyond the scope of the present paper: it would require information on the time evolution of the density profile with smaller time steps, and to use the time evolved profile for a detailed numerical study of the neutrino conversion in a regime where all the three oscillation terms are relevant.

In the late post-shock phase the Earth effect is further reduced in amplitude and ultimately goes to zero together with P_H , starting with the lower energy part of the neutrino spectrum and including higher energies as time passes. In Fig. 6 we see the same feature at $E = 22$ MeV as in fig. 4, marking the transition to completely adiabatic conversion in the high-density resonance at late post-shock times.

FIG. 7: Same as fig. 6 for $\sin^2 \theta_{13} = 10^{-5}$. The conversion is non-adiabatic at all times, and so the oscillations in the Earth never vanish. They differ from the case of a Fe-core supernova in the sign at early times ($t \sim 60$ ms, around the neutronization peak): negative for ONeMg-core supernovae and positive for Fe-core ones.

If θ_{13} is small, the Earth effect is non-vanishing at all times (fig. 7), because the high-density resonance remains completely non-adiabatic. The double sign flip discussed above happen in this case as well, implying the same possibility for amplitude modulation and/or sign changes as for the scenario with intermediate θ_{13} . The major difference with respect to a Fe-core supernova is the different sign of the Earth effect at $t \sim 60$ ms, while at later times the two cases are similar.

FIG. 8: Same as fig. 6 for $\sin^2 \theta_{13} = 10^{-2}$. After the shock reaches the He shell, the conversion is essentially adiabatic and the Earth effect disappears. In a Fe supernova the effect would be zero at all times.

For large θ_{13} , oscillations in the Earth practically disappear with the shock passage through the high-density resonance (fig. 8), due to the adiabatic character of this resonance in the post shock regime. This differs strongly from the case of a Fe-core supernova, where for the same values of θ_{13} (and the same normal mass hierarchy) the Earth effect is zero at all times.

The sudden or progressive disappearance of the Earth oscillations is unique of a ONeMg-core supernova. For a Fe-core supernova the effect is either constantly non-zero or it appears at late times ($t \gtrsim 5$ s) due to the shock wave propagation through the resonance layer [3].

We find similar results for other directions of propagation inside the Earth. The Earth effect is stronger for deeper trajectories inside the Earth, reaching about 40% size at ~ 70 MeV for neutrinos moving along the diameter of the Earth.

B. Spectra

Finally, we find it useful to show the energy spectrum of the electron neutrino flux in a detector for a ONeMg-core supernova. It is given in the left column of fig. 10, for different times and different values of θ_{13} . The right column of the figure illustrates the same spectra, but with the oscillation effects calculated for a Fe-core supernova (from [3]) [71].

The figure shows two dramatic signatures of a ONeMg-core supernova in the high luminosity ν_e flux from neutronization ($t \simeq 60$ ms), that were already pointed out in [7]: the lack of suppression of the flux, regardless of the value of θ_{13} , and the step in the spectrum at $E \sim 12$ MeV, due to neutrino-neutrino scattering. The exact position and shape of the step in the energy spectrum would require a full detailed calculation that is not done here. However, using the results in [25] we have checked that these quantities are rather independent of the details of the original neutrino spectra and of the matter density profile, and this assures the validity of fig. 10 for illustration.

A third, well visible, feature is the negative sign of the Earth effect in the neutronization peak for a ONeMg-core supernova in contrast with the positive sign for a Fe-core one. This could be precious to distinguish the two progenitor types if θ_{13} is small or unknown: indeed for small θ_{13} the neutronization peak is unsuppressed for both types and the step in the spectrum for the ONeMg-core supernova could be masked by the small statistics and poor energy resolution if it is near the threshold of the detector (e.g., a 7 MeV threshold for a water Cherenkov detector). The Earth effect, instead, is largest at high energy, where the energy resolution is better.

The features discussed for a ONeMg-core supernova in the post-shock phase, namely the progressive decrease of the survival probability and of the Earth effect for intermediate θ_{13} , are present, but not visible at the scales used in fig. 10. They are of the order of $\sim (5 - 25)\%$ depending on the energy and of the specific value of θ_{13} .

Notice that, while p can decrease with time by a factor of 2 or more (fig. 4), the net effect on the neutrino spectrum is modest. This is due to the fact that p is small in value: the observed ν_e flux is dominated by the originally produced ν_μ, ν_τ fluxes, and therefore it is impacted only at the level of tens of per cent by even major changes in the surviving ν_e component.

V. DISCUSSION

ONeMg-core collapses amount to 4% to 20% of all supernovae in the local universe [8]. If one of them happens in our galactic neighborhood, the observed conversion effects will be a unique way to confirm the presence of the step in density at the base of the He shell and the faster shock propagation relative to a Fe-core supernova. The main oscillation signatures for both supernova types are summarized in fig. 9. In more detail, the presence of the step characteristic of a ONeMg-core supernova would be confirmed if:

- θ_{13} is known to be large and the neutronization peak does not disappear. Disappearance is predicted for the smooth profile of a Fe-core supernova, where the neutrino propagation is completely adiabatic.

- θ_{13} is intermediate, small, or unknown, and data indicate a ν_e survival probability larger than ~ 0.32 in the first 100-150 ms of the burst. This indicates that at least part of the produced ν_e 's exit the star in the state ν_1 , which can not happen for the smooth density profile of a Fe-core supernova.
- The Earth effect is negative in coincidence with the neutronization ν_e peak ($t \sim 60$ ms). This is another sign that ν_e 's are converted into ν_1 's.
- Shock effects – regardless of when they happen – evidence a change from less adiabatic to more adiabatic conversion as time passes. Such a change manifests itself as decrease of the ν_e survival probability (increase of ν_e - ν_x permutation) and decrease in the amplitude of the oscillations inside the Earth. In absence of the step, the shock passage would have the opposite effect [1].

The timing of the shock effects will test the scenario of the faster shock propagation unambiguously. These effects are characterized by features that move through the neutrino spectrum, from low to high energy, as time passes. Such features can, in principle, provide a valuable measurement of the speed of the shock.

FIG. 9: Summary of the oscillation signatures of ONeMg-core supernovae compared to Fe-core supernovae at different times. They refer to the ν_e channel for the normal mass hierarchy; p is the ν_e survival probability. The shaded areas represent the pre-shock phase, defined as the time interval before the shock front reaches the location of the MSW resonances, while the white regions (“shocked”) indicate the later times.

The time-dependent features induced by the shock wave on the observed ν_e signal will also give information on θ_{13} . In particular:

- A large θ_{13} ($\sin^2 \theta_{13} \gtrsim 3 \cdot 10^{-3}$) will be singled out if both the survival probability p and the amplitude

of oscillations in the Earth drop quickly to zero in the post-shock phase (within ~ 300 ms).

- An intermediate θ_{13} ($\sin^2 \theta_{13} \sim 3 \cdot 10^{-5} - 3 \cdot 10^{-3}$) is identified by the fact that both p and the amplitude of oscillations in the Earth decrease more slowly, and may vanish only in the late post-shock phase, $t \gtrsim 700$ ms. This late transition will begin with the lower energy neutrinos and extend to higher energy as time passes. The probability p changes in three distinct steps corresponding to pre-shock, early and late post-shock. For $\sin^2 \theta_{13} \sim 3 \cdot 10^{-4} - 3 \cdot 10^{-3}$ a similar three-steps behavior characterizes the Earth oscillations at least in part of the energy spectrum (fig. 6).
- A small θ_{13} ($\sin^2 \theta_{13} \lesssim 3 \cdot 10^{-5}$) will appear from the fact that p never vanishes, but only drops from $p \sim 0.68$ to $p \sim 0.32$ after the shock reaches the base of the He shell. The Earth oscillations also remain present at all times, either unchanged or with subtle time modulations. These can be a temporary flip of sign and/or a temporary reduction or even disappearance of the amplitude. They are due to the change of P_L from 1 to 0, passing by the critical value of $P_L = 1/2$, for which the Earth effect disappears.

In the absence of Earth shielding, one would need to measure the value of the survival probability p and look for its time variations. Both could be difficult because the neutrino fluxes in the different flavors at the neutrinosphere are uncertain and evolve with time, a fact that can mask time features due to flavor conversion. The non-disappearance of the neutronization peak and step-like features that move from low to high energy, like that in Fig. 4, would probably be the easiest to distinguish.

If a detector is shielded by the Earth, instead, the chances to distinguish the early shock effects are much better, since the oscillatory distortions of the neutrino spectrum induced by the Earth can not be mimicked by any other phenomenon [56, 57], and their phase is well known thanks to the relatively precise measurements of the parameters Δm_{21}^2 and θ_{12} .

If a supernova is optically obscured, neutrino data will be the only source of information on the nature of the progenitor. In such an event, searches for the oscillation signatures of an ONeMg-core supernova would have an even higher importance. Information from data at early times will be complemented and substantiated by the data at late times, $t \gtrsim 5$ s, where shock effects are expected for a Fe-core supernova and θ_{13} in the intermediate and large range [2, 4, 5, 6]. For example, the late appearance of oscillations in the Earth would exclude an ONeMg-core supernova. For small θ_{13} any shock wave signature disappears for a Fe-core supernova, making it more challenging to distinguish between Fe-core and ONeMg-core types. Discrimination is still possible from looking for signs of non-zero P_L in the pre-shock phase,

which is typical of an ONeMg-core supernova. These are a large ν_e survival probability, $p \gtrsim 0.32$, and the negative Earth effect around the neutronization peak.

In any event, the oscillations discussed here will be crucial for the correct interpretation of data from an ONeMg-core supernova, aimed at reconstructing the original neutrino fluxes, which are so important to test the theory of core collapse, reconstruct the mass of the neutron star and – indirectly – its equation of state, and to discuss the conditions for supernova nucleosynthesis.

Before concluding, a word of caution is necessary about the validity of our results. They were obtained assuming that the conversion of neutrinos in the star can be described in terms of transitions between the eigenstates of the Hamiltonian – which justifies Eq. (6) – with the transition probabilities as discussed in sec. III. While all the literature available at this moment supports this prescription, a confirmation from a detailed numerical study of the problem still lacks. We expect that, after such study is done, our results remain valid at least in the main message that a distinctive pattern of neutrino conversion is associated with a ONeMg-core supernova, characterized by high survival probability of ν_e due to the step in density at the base of the He shell and by early shock effects that drive the conversion towards stronger flavor conversion.

Our work is focused exclusively on the case of neutrinos and normal mass hierarchy, for two main reasons. The first is that the case of normal hierarchy is particularly simple in its oscillation pattern, and has also been studied in the most detail for ONeMg-core supernovae in the pre-shock phase [7]. This makes it an ideal choice for an initial study of the oscillation signatures of a ONeMg-core supernova. The second motivation is that the neutrino channel is especially interesting for a ONeMg-core supernova because of the very distinctive signature in the neutronization peak, $t \simeq 60$ ms (fig. 10). General arguments on neutrino conversion in the dense matter of a supernova (see e.g. [24]) suggest that the features expected for neutrinos and normal hierarchy should appear – same in character but different in the details – also in the other cases of antineutrinos and/or inverted mass hierarchy. Specifically, for the inverted hierarchy all the phenomena associated with the high density resonance will appear in the antineutrino channel. Also, neutrino self-interaction will induce strong flavor conversion on both neutrinos and antineutrinos within the first few hundreds of Km of radius (see e.g. [40]).

The generalization of our results to other combinations of channels (neutrinos and antineutrinos) and hierarchies require a more in-depth modeling of the effects of neutrino-neutrino scattering, a difficult task that receives

further motivation from this work. The combination of observations in different channels can only strengthen the conclusions that a single channel can give.

This brings us to the question of what detector is best for the study of the effects we have discussed. For the case considered here (neutrino channel), the optimal setup is an experiment that can detect electron neutrinos exclusively. Liquid argon technology is very suitable for this. To have sufficient statistics in time bins ~ 100 ms wide, necessary to test the fast time variations found here, large volumes are required. Thus, the massive liquid argon project MODULAr (20 Kt mass, corresponding to $\sim 10^3$ ν_e events from a galactic supernova [59]) and the even more ambitious GLACIER [60] (up to 100 Kt mass, i.e. $\sim 6 \cdot 10^3$ ν_e events) would be very valuable. Considering that no large ν_e detector is currently active, after the closure of SNO [61], it is extremely important to emphasize the importance of having new detectors of this type to study supernovae, and our paper contributes in this direction. Of course, the best out of a supernova observation would be obtained from combining data from different detection channels. The effect on antineutrinos due to the step in the density of an ONeMg-core supernova would be very well visible in the inverse beta decay events at SuperKamiokande (see e.g., [62]) and at its larger versions, UNO, HyperKamiokande and MEMPHYS [63, 64, 65], as well as at the planned liquid scintillator experiment LENA [66]. With several detectors running, there is a substantial chance that at least one of them will be shielded by the Earth [56, 67] and thus will have an enhanced sensitivity to neutrino flavor conversion.

CL acknowledges support from Arizona State University, from the RIKEN BNL Research Center (RBRC), and from the ORNL grant of the Institute of Nuclear Theory (INT) of Seattle, where this work was initiated. The INT is also thanked for hospitality during part of the time of preparation of this work. CL is grateful to H. Duan, A. Marrone and A. Mirizzi for useful clarifications and discussions. BM and HTJ are grateful to K. Nomoto for providing them his stellar progenitor data and to A. Marek for his contributions to the microphysics used in the supernova runs. The project in Garching was supported by the Deutsche Forschungsgemeinschaft through the Transregional Collaborative Research Centers SFB/TR 27 “Neutrinos and Beyond” and SFB/TR 7 “Gravitational Wave Astronomy”, and the Cluster of Excellence EXC 153 “Origin and Structure of the Universe” (<http://www.universe-cluster.de>). The supernova computations were performed at the High Performance Computing Center Stuttgart (HLRS) under grant number SuperN/12758.

- [68] For simplicity of language, throughout the paper P_H and P_L will be referred to as “jumping probabilities”, and the expression “adiabatic” for the neutrino propagation will be used in connection to them. We stress that, while

this terminology is accurate for the MSW resonances in the post-shock case, in the pre-shock phase it is simply an effective description, and does not correspond to the physics of the neutrino propagation, due to collective effects.

- [69] A major, but trivial, difference with respect to the plots of ref. [7] is due to the fact that we use the probabilities at Earth, averaged over oscillations, while the plots in [7] refer to a radial distance of 5000 Km.
- [70] The choice of 60 ms is motivated by its marking the peak of the neutronization flux. The density profile was not

calculated for this precise instant of time, and so the profile at $t = 50$ ms has been used as a very reasonable approximation.

- [71] We emphasize that the results in both columns of fig. 10 were calculated using the same original fluxes shown in fig. 2, the only difference being in the flavor conversion. While not realistic (the original spectra are different for ONeMg-core and Fe-core supernovae), this is useful for the illustration of the distinctive oscillation effects of the two types of supernovae

FIG. 10: Left column: predicted spectra of the ν_e flux in a detector for ONeMg-core supernova, inclusive of oscillations in the star and in the Earth (nadir angle 60 degrees). Right column: the same spectra, but with the oscillation effects that are characteristic of a Fe-core supernova. From the upper to lower panel: $\sin^2 \theta_{13} = 0.01, 6 \cdot 10^{-4}, 10^{-5}$. The thick curves refer to different times: $t = 60, 450, 700 \text{ ms}$ (solid, short dashed, and long dashed, respectively). For $t = 60 \text{ ms}$ we also show the spectrum in absence of Earth shielding (thin solid line). The vertical axis has units of $\text{MeV}^{-1} \text{ s}^{-1}$.
